April 2014

Abstract

We investigate the effects of uncertainty shocks on unemployment dynamics in the post-WWII U.S. recessions via non-linear (Smooth-Transition) VARs. The relevance of uncertainty shocks is found to be much larger than that predicted by standard linear VARs in terms of i) magnitude of the reaction of the unemployment rate to such shocks, and ii) contribution to the variance of the prediction errors of unemployment at business cycle frequencies. We discuss the ability of different classes of DSGE models to replicate our results.

Keywords: Uncertainty shocks, Unemployment Dynamics, Smooth Transition Vector-AutoRegressions, Recessions.

JEL codes: C32, E32, E52.

1 Introduction

"There's pretty strong evidence that the rise in uncertainty is a significant factor holding back the pace of recovery now. [...] research shows that heightened uncertainty slows economic growth, raises unemployment, and reduces inflationary pressures. [...] There's no question that slow growth, high unemployment, and significant uncertainty are challenges for monetary policy." John Williams, President and Chief Executive Officer of the Federal Reserve Bank of San Francisco, FRBSF Economic Letter, January 21, 2013.

The U.S. unemployment rate has experienced a substantial upswing during the 2007-2009 economic crisis, moving from 4.4% in May 2007 to 10.1% in October 2009. Since then, the recovery of the labor market has been marked but not full. In January 2013, unemployment was assessed to be some 2% larger than its longer-run value by most FOMC participants (Yellen, 2013). Clearly, the identification of the drivers behind the evolution of the U.S. unemployment rate is of primary importance to policymakers.¹

This paper investigates the impact of uncertainty shocks on unemployment during U.S. post-WWII recessionary episodes. Since the seminal contribution by Bloom (2009), a large number of papers have been concerned with the role of uncertainty at a macroeconomic level.² Part of the literature has studied the impact of uncertainty shocks with Dynamic Stochastic General Equilibrium models.³ A related empirical literature has dealt with the identification of uncertainty shocks by employing *linear* VAR

¹According to the Federal Reserve Act, the promotion of maximum sustainable output and employment is one of the two ultimate goals of the Federal Reserve, the other one being the promotion of stable prices. In December 2012, the FOMC decided "[...] to keep the target range for the federal funds rate at 0 to 1/4 percent and currently anticipates that this exceptionally low range for the federal funds rate will be appropriate at least as long as the unemployment rate remains above 6-1/2 percent, inflation between one and two years ahead is projected to be no more than a half percentage point above the Committee's 2 percent longer-run goal, and longer-term inflation expectations continue to be well anchored." See http://www.federalreserve.gov/newsevents/press/monetary/20121212a.htm.

²A survey by Bloom, Fernández-Villaverde, and Schneider (2013) discusses the variety of channels through which uncertainty may affect economic agents' decisions.

³A non-exhaustive list of studies includes Fernández-Villaverde, Guerrón-Quintana, Rubio-Ramírez, and Uribe (2011), Bloom, Floetotto, Jaimovich, Saporta-Eksten, and Terry (2012), Benigno, Benigno, and Nisticò (2012), Mumtaz and Theodoridis (2012), Bianchi and Melosi (2013), Bachmann and Bayer (2013), Bachmann, Elstner, and Sims (2013), Basu and Bundick (2012), Leduc and Liu (2013), Christiano, Motto, and Rostagno (2014).

models. Recent contributions include Bloom (2009), Alexopoulos and Cohen (2009), Bachmann, Elstner, and Sims (2013), Mumtaz and Theodoridis (2012), Baker, Bloom, and Davis (2013), Gilchrist, Sim, and Zakrajsek (2013), Leduc and Liu (2013), Colombo (2013), Nodari (2013), Mumtaz and Surico (2013).⁴ Linear VAR frameworks are standard tools in the empirical macroeconomic literature. However, the U.S. unemployment rate has been found to be characterized by asymmetric dynamics across different phases of the business cycle (Koop and Potter, 1999; van Dijk, Teräsvirta, and Franses, 2002; Morley and Piger, 2012; Morley, Piger, and Tien, 2013), a stylized fact which naturally leads to the adoption of non-linear frameworks. Moreover, uncertainty is typically high during recessions, when unemployment also tends to increase abruptly (Jurado, Ludvigson, and Ng, 2013). For these reasons, recessionary episodes are very likely to be quite informative phases for the identification of the effects of uncertainty shocks on unemployment.

We elaborate on this point by working with a non-linear framework suited to isolate the impact of uncertainty shocks during recessions.⁵ To this aim, we model U.S. quarterly data on uncertainty, unemployment, and other standard macroeconomic variables with Smooth Transition Vector AutoRegression (STVAR) models. The STVAR set up conveniently allows us to isolate recessionary episodes while retaining enough informa-

⁴These contributions employ small-scale VARs. However, the importance attributed to uncertainty shocks does not seem to be due to omitted information. Stock and Watson (2012) employ Dynamic Factor models to process a database composed by 200 U.S. economic series. They find uncertainty shocks to be quite relevant for explaining the post-WWII macroeconomic dynamics.

⁵Section 2 develops this argument further. For a paper dealing with instabilities in the macroeconomic effects of uncertainty shocks via a rolling-window VAR approach, see Beetsma and Giuliodori (2012). An investigation dealing with instabilities via a time-varying VAR approach is proposed by Benati (2013). A related approach is that by Enders and Jones (2013), who estimate Logistic Smooth Transition Autoregressive Models for a number of macroeconomic indicators. They isolate different effects of uncertainty shocks in presence of "high" vs. "low" uncertainty. Differently, we focus on the effects of uncertainty shocks during recessions (i.e., phases of "low" economic growth) and contrast such effects to what is typically found with standard linear VARs. In doing so, we employ a multivariate framework to model the systematic interaction among policy-relevant macroeconomic indicators such as inflation, unemployment, and a short-term interest rate. This enables us to control for spurious evidence of non-linearity possibly arising when omitting to model systematic interactions among structurally related variables.

tion to estimate a richly parametrized VAR framework. To understand to what extent non-linearities are important for uncovering the effects of uncertainty shocks, we then contrast the predictions of the non-linear STVAR models conditional on recessions with those produced with standard linear VARs.

Our main results are the following. First, we find that the impact of uncertainty shocks on unemployment is substantially underestimated if one does not take into account that they typically occur in recessions. A linear VAR model returns estimates suggesting that a one standard deviation increase in the VIX, our proxy for uncertainty, may induce a reaction of the unemployment rate of about 0.17 percentage points four quarters after the shock, and of about 0.14 percentage points eight quarters after such shock. The non-linear VAR reveals that the same shock, when hitting the economy during a recession, is estimated to induce a much larger (and statistically different) increase in unemployment of 0.36 percentage points four quarters after the shock, and 0.41 two years after the shock. Evidence of non-linear dynamics is also found for the policy rate and inflation. The asymmetry result holds not only for unemployment, but also for a number of alternative real activity indicators, including hours, output, investment, durable and nondurable consumption. Second, consistently with the previous findings, the contribution of uncertainty shocks to the forecast error variance decomposition of the unemployment rate at business cycle frequencies is estimated to be (at least) three times larger in a non-linear VAR model. Interestingly, such shocks turn out to be more powerful than monetary policy shocks as a driver of the U.S. unemployment rate. A battery of checks, dealing with a different data-frequency, a number of additional variables in our VARs, different identification schemes, different empirical proxies for uncertainty, and a shorter sample omitting the zero-lower bound, confirm the robustness of our results. Wrapping up, the non-linear VAR analysis suggests that uncertainty shocks may be markedly more costly than previously estimated via linear

frameworks.6

Overall, our findings corroborate those presented in previous contributions on the asymmetries characterizing the evolution of the unemployment rate over the business cycle. Koop and Potter (1999) perform an extensive model comparison involving linear and non-linear models for the U.S. unemployment rate. They find clear evidence in favor of a non-linear threshold autoregressive model featuring two distinct regimes. In their survey on STVAR models, van Dijk, Teräsvirta, and Franses (2002) provide further evidence in favor of asymmetric dynamics of the U.S. unemployment rate across different regimes. Morley and Piger (2012) construct an indicator of the U.S. business cycle by averaging a variety of competing linear and non-linear statistical frameworks. The resulting indicator clearly points to variations in the cycle larger during recessions than in expansionary periods. Interestingly, their measure displays an asymmetric shape and it is shown to be closely related to the unemployment rate. Importantly, Morley, Piger, and Tien (2013) show that the relevance of non-linearities for modeling an indicator of the business cycle survives also when considering a multivariate approach.

Our results are also of interest from a modeling standpoint. Gilchrist and Williams (2005) show that, in a standard real business cycle (RBC) set up featuring a Walrasian labor market, uncertainty shocks are expansionary because they negatively affect house-holds' wealth, therefore increasing households' marginal utility of consumption and labor supply. Leduc and Liu (2013) show that this conclusion is overturned when some real frictions are added to the framework. In particular, in a model with search frictions in the labor market, positive uncertainty shocks negatively affect potential output. This

⁶In principle, it is possible that the countercyclical evolution of uncertainty is endogenous and due to movements in the business cycle, more than a cause of such movements. Bachmann and Moscarini (2012) propose a model in which strategic price experimentation during bad economic times (due to first moment shocks) leads to a higher dispersion of firms' profits. Baker and Bloom (2012) use natural disasters and events like terrorist attacks and unexpected political shocks to isolate exogenous increases in uncertainty in a panel of countries. They find the contribution of second moment shocks to explain at least half of the variation in real GDP growth.

occurs because firms pause hiring new workers when uncertainty hits the economy due to the lower expected value of a filled vacancy. As a consequence, firms post a lower number of vacancies, so inducing a drop in the job finding rate and an increase in the unemployment rate. In presence of sticky prices in the intermediate sector, this conclusion is reinforced. Facing an uncertainty shock, aggregate demand drops, so leading firms to lower their relative prices. Such decline reduces even further the value of a vacancy, therefore raising unemployment even more. Leduc and Liu (2013) notice that, in a sticky price framework, an uncertainty shock lowers inflation as well, and therefore can be interpreted as a demand shock. A similar conclusion is reached by Basu and Bundick (2012), who show that sticky prices are important to generate a contraction in output and its components after an exogenous increase in uncertainty. Our empirical findings support the conclusions by these two latter papers, as we show that uncertainty shocks are demand shocks. Hence our results suggest that labor market frictions and sticky prices are relevant frictions to interpret the macroeconomic effects of uncertainty shocks during recessions.

The structure of the paper is the following. Section 2 offers statistical support in favor of a non-linear relationship between unemployment and uncertainty, presents the Smooth Transition VAR model employed in our analysis, and explains the reasons behind our choice of focusing on recessions. Section 3 presents our results, whose robustness is documented in Section 4. Section 5 provides further evidence on the importance to employ non-linear models when dealing with uncertainty shocks. Section 6 concludes.

2 Empirical investigation

The aim of this Section is twofold. First, we present our Smooth-Transition VAR model. Second, we discuss the reasons behind our focus on U.S. recessions.

2.1 Data and methodology

As anticipated in the Introduction, we identify the macroeconomic effects of uncertainty shocks during post-WWII U.S. recessions by modeling some selected U.S. macroeconomic series with a Smooth-Transition VAR framework. Granger and Teräsvirta (1993) offer a presentation on STVARs and discuss some issues related to their estimation. A survey on recent developments in this area is proposed by van Dijk, Teräsvirta, and Franses (2002).

Formally, our STVAR model reads as follows:

$$\mathbf{X}_{t} = F(z_{t-1})\mathbf{\Pi}_{R}(L)\mathbf{X}_{t} + (1 - F(z_{t-1}))\mathbf{\Pi}_{NR}(L)\mathbf{X}_{t} + \boldsymbol{\varepsilon}_{t}, \qquad (1)$$

$$\boldsymbol{\varepsilon}_t \sim N(0, \boldsymbol{\Omega}_t),$$
 (2)

$$\boldsymbol{\Omega}_t = F(z_{t-1})\boldsymbol{\Omega}_R + (1 - F(z_{t-1}))\boldsymbol{\Omega}_{NR}, \qquad (3)$$

$$F(z_t) = \exp(-\gamma z_t) / (1 + \exp(-\gamma z_t)), \gamma > 0, z_t \sim N(0, 1).$$
(4)

where \mathbf{X}_t is a set of endogenous variables which we aim to model, $F(z_{t-1})$ is a logistic transition function which captures the probability of being in a recession and whose smoothness parameter is γ , z_t is a transition indicator, $\mathbf{\Pi}_R$ and $\mathbf{\Pi}_{NR}$ are the VAR coefficients capturing the dynamics of the system during recessions and non-recessionary phases (respectively), $\boldsymbol{\varepsilon}_t$ is the vector of reduced-form residuals having zero-mean and whose time-varying, state-contingent variance-covariance matrix is $\mathbf{\Omega}_t$, and $\mathbf{\Omega}_R$ and $\mathbf{\Omega}_{NR}$ are covariance matrices of the reduced-form residuals computed during recessions and non-recessions, respectively.

In short, this model assumes that our endogenous variables can be described as a linear combination of two linear VARs, i.e., one suited to describe the state of the economy during recessions and the other to be interpreted as a "catch all" vector modeling the remaining phase(s). Conditional on the standardized transition variable z_t , the logistic function $F(z_t)$ indicates the probability of being in a recessionary phase.⁷ The transition from a regime to another is regulated by the smoothness parameter γ . Large values of this parameter imply abrupt switches from a regime to another. Viceversa, moderate values of γ enable the economic system to spend some time in each regime before switching to the alternative one. Importantly, the STVAR model allows for non-linear effects as for both the contemporaneous relationships and the dynamics of our economic system.

Our baseline analysis hinges upon the vector $\mathbf{X}_t = [vix_t, \pi_t, u_t, R_t]'$, where vix_t stands for the VIX index, our proxy for uncertainty, π_t stands for inflation, u_t is the unemployment rate, R_t is a policy rate. The Chicago Board Options Exchange Market Volatility Index (the VIX index) measures the implied volatility of the S&P500 index options. This index, often referred to as "fear index", represents a measure of market expectations of stock market volatility at time t over the next 30-day period. Before 1986 this index is unavailable. Following Bloom (2009), we compute pre-1986 monthly returns volatilities by employing the monthly standard deviation of the daily S&P500 index normalized to the same mean and variance as the VIX index from 1986 onward. Inflation is computed as the annualized quarter-on-quarter percentage growth rate of the implicit GDP deflator. Unemployment is the monthly civilian unemployment rate. The policy rate is the federal funds rate. Quarterly observations of monthly data are constructed via quarterly averaging. The sample spans the 1962Q3-2012Q3 period, 1962Q3 being the first available quarter as for the uncertainty index. The source of our data is the FRED database on the Federal Reserve Bank of St. Louis' website.⁸

⁷As suggested by van Dijk, Teräsvirta, and Franses (2002), one may think of this model as a regime-switching framework that allows for two different regimes associated with extreme values of the transition function, i.e., "recessions" when $F(z_t) = 1$, which (under the assumption of $\gamma > 0$) occurs for large negative values of z_t (formally, when $z_t \to -\infty$), and "non-recessions" when $F(z_t) = 0$ (which realizes when $z_t \to \infty$). Alternatively, one may think of a "continuum" of regimes, each associated with a different value of the transition function $F(z_t)$. For simplicity, we will refer in this paper to the two regime-interpretation.

⁸The plot of the series is provided in the Appendix. Following the recent macroeconomic literature,

We employ this dataset to verify the presence of non-linearities in the unemploymentuncertainty relationship. We run two tests. The first is based on a regression of unemployment rate on its own lags, uncertainty, and interaction terms between these two variables as regressors. As shown by Luukkonen, Saikkonen, and Teräsvirta (1988), the assumption of linearity is rejected if the coefficients of the interaction terms are jointly different from zero. To detect non-linear dynamics at a multivariate level, we then perform the test proposed by Teräsvirta and Yang (2013). Their framework is particularly suited for our analysis since it amounts to test the null hypothesis of linearity versus a specified nonlinear alternative, that of a (Logistic) Smooth Transition Vector AutoRegression with a single transition variable. In performing this multivariate test, we consider our vector of endogenous variables \mathbf{X}_t . Both tests suggest a clear rejection of the null hypothesis of linearity. Technical details on these tests and their implementation are reported in the Appendix.

The identification of exogenous variations of the uncertainty index is achieved via the widely adopted Cholesky-assumption. Given the ordering of the variables in X_t , this implies that we allow for on-impact macroeconomic effects by our identified uncertainty shocks. While being a common assumption in the literature, it must be noted that demand and supply shocks influencing the equilibrium values of our macroeconomic indicators may also influence uncertainty within a quarter. Hence, no recursive ordering is probably right in this context. Moreover, ordering the VIX first in our vector implies that we are attributing all the one-step-ahead forecast error in the VIX to uncertainty shocks. Consequently, our results should be interpreted as providing an upper bound on the effects of uncertainty shocks.⁹ Importantly, in our Appendix we show that

we model the unemployment rate in levels. For a univariate analysis focusing on a logistic transformation of the unemployment rate and confirming the superiority of a non-linear threshold model, see Koop and Potter (1999).

⁹One of our robustness checks (presented in the next Section) deals with a different ordering of our variables with uncertainty ordered last. The estimates on the macroeconomic effects of uncertainty shocks in recessions turn out to be robust to this alternative ordering. In our VAR, uncertainty is

our results are robust to the employment of monthly data, which make the recursive identifying restriction more plausible.

A key role is played by the transition variable z_t . Following Auerbach and Gorodnichenko (2012), Bachmann and Sims (2012), and Berger and Vavra (2014), we employ a standardized moving average involving seven realizations of the quarter-on-quarter real GDP growth rate.¹⁰ Auerbach and Gorodnichenko (2012) suggest to fix γ to ease the estimation of the remaining parameters of highly non-linear STVARs like ours. We calibrate the smoothness parameter γ by referring to the duration of recessions in the U.S. according to the NBER business cycle dates (17 percent of the time in our sample according to the dating proposed by the NBER). Then, we define as "recession" a period in which $F(z_t) \ge 0.83$, and calibrate γ to obtain $\Pr(F(z_t) \ge 0.83) \approx 0.17$. This metric implies a calibration $\gamma = 1.75$, which is quite close to the 1.5 value employed by Auerbach and Gorodnichenko (2012), Bachmann and Sims (2012), and Berger and Vavra (2014).¹¹

The transition function $F(z_t)$ is shown in Figure 1.¹² Clearly, high realizations of $F(z_t)$ tend to be associated with NBER recessions. Notice that the a priori choice of a transition function provides us with an information that we would otherwise need to recover from the data by estimating a latent factor dictating the switch from a state to another, as it occurs when Markov-Switching VAR frameworks are taken to the data.

captured by the VIX, which is a "second moment" by construction. Differently, we do not model the evolution of the second moments of other structural shocks in our vector. We notice, however, that our VAR features a time-varying covariance matrix of its residuals. Most likely, this captures the bulk of the volatility of the structural shocks other than the uncertainty shock. Hence, while in principle our "uncertainty shock" might pick up some unmodeled volatility of the remaining structural shocks, this case is likely to be negligible from an empirical standpoint.

¹⁰The transition variable z_t is standardized to render our calibration of the slope parameter γ comparable to the ones employed in the literature.

¹¹This implies labeling as "recessions" periods in which $z_t \leq -0.91$. Our results are robust to alternative calibrations for γ implying a frequency of recessions ranging from 10 to 25 percent, where the lower bound is determined by the minimum amount of observations each regime should contain according to Hansen (1999).

¹²The Appendix shows that our transition function $F(z_t)$ is extremely close to that employed in Auerbach and Gorodnichenko (2012) and Bachmann and Sims (2012).

Our (linear/non-linear) VAR features three lags. This choice is justified by the Akaike criterion when applied to a linear model estimated on the full-sample 1962Q3-2012Q3. Results are robust to reasonable variations of the number of lags (results available upon request).

Given the high non-linearity of the model, we estimate it by the Monte-Carlo Markov-Chain simulation method proposed by Chernozhukov and Hong (2003). Our Appendix reports details on the estimation methodology.¹³ Notice that the indicator variable z_t is not embedded in our vector of modeled variables X_t . As discussed in Koop, Pesaran, and Potter (1996), absent any feedback from the endogenous variables to z_t , we can compute the impulse responses to an uncertainty shock by assuming regimespecific linear VARs. In other words, we will compute the macroeconomic reactions to uncertainty shocks by assuming to start in a recession and to remain in such state, i.e., we assign a zero-probability to switch to a non-recessionary phase. This choice is justified by our interest to focus on the short-run dynamics of the U.S. economic system. Moreover, it has some desirable implications, i.e., the impulse responses will depend neither on initial conditions nor on the size or sign of the uncertainty shock. To give some statistical support to our choice, we regress the estimated uncertainty shocks (conditional on our linear VAR) on a constant and three lags of the transition variable. The p-value associated to the F-test on the predictive power of the transition variable as for future uncertainty shocks reads 0.10. The reason behind this result is the presence of the unemployment rate in our VAR. We corroborate this hypothesis by estimating uncertainty shocks with a trivariate VAR featuring uncertainty, inflation, and the fed-

¹³Note that, in principle, this model could be estimated by maximum-likelihood. However, as pointed out by Auerbach and Gorodnichenko (2012) and Teräsvirta and Yang (2013), finding the optimum of the target function may be problematic due to its flatness in some directions and its many local optima. The algorithm put forth by Chernozhukov and Hong (2003) has two attractive features in our set-up: i) it finds the global optimum of the likelihood of the model as well as distributions of the parameter estimates under general conditions; ii) it is computationally efficient. An alternative to the MCMC pursued in our paper is the search of suitable starting values for the vector of parameters of interest (Teräsvirta and Yang, 2013).

eral funds rate only. When regressing such 'shocks' obtained with this VAR without unemployment, the p-value turns out to be 0.03, an evidence supporting our conjecture on the informativeness of the unemployment rate in our VAR. Further considerations on the computation of our impulse responses are proposed in our Robustness checks Section.

It is worth stressing that our STVAR framework exploits information coming from all the observations in the dataset, which are "indexed" by the transition function $F(z_t)$. Differently, the estimation of two different VAR models (one for each given regime) would imply more imprecise estimates due to the smaller number of observations, especially for recessionary periods.

2.2 Focus on recessions

The focus of our analysis is on recessions. Two reasons lie behind this choice. First, peaks in uncertainty measures often occur during recessions. Differently, expansionary phases are characterized by "heterogeneous signals" associated with any measure of uncertainty (e.g. high vs. low realizations with respect to their sample means). Figure 2 plots four indicators of uncertainty often employed in empirical studies, i.e., the VIX (a volatility index related to the U.S. stock market), widely used as a proxy for uncertainty at a macroeconomic level (e.g., Bloom, 2009, Leduc and Liu, 2013); a common macro uncertainty factor estimated by Jurado, Ludvigson, and Ng (2013), which is a factor modeling the one-year ahead forecast error related to a large dataset of U.S. data; the Corporate Bond Spread (computed as the difference between the Baa 30 year-yield and the Treasury yield at a comparable maturity), employed by Bachmann, Elstner, and Sims (2013); and the Economic Policy Uncertainty index developed by Baker, Bloom, and Davis (2013), which is based on information coming from a set of U.S. newspapers and survey data. The evolution of these indicators confirms that recessions, as identified

by the NBER, are characterized by comovements in the same direction of all measures of uncertainty. In contrast, ups and downs of these indicators are far from being rare during NBER expansions. Hence, a priori, recessions seem to carry cleaner information on the effects of uncertainty shocks on the macroeconomic environment than expansions. A formal support to this conjecture is offered by a recent work by Jurado, Ludvigson, and Ng (2013), who carefully estimate uncertainty factors by modeling the variability of the purely unforecastable components of future values of a large set of economic indicators. Their estimated uncertainty factors are shown to peak in correspondence to three big post-WWII recessions (1973-74, 1981-82, 2007-2009). More generally, they find macro uncertainty to be higher in recessions than in non-recessions years. Finally, while the identification of recessions appears to be uncontroversial in the literature, the identification of expansionary phases has proved to be debatable. In particular, the traditional two state-classification of the U.S. business cycle based on the identification of recessions and expansions has been challenged by, among others, Sichel (1994), van Dijk and Franses (1999), Galvão (2002), and Morley, Piger, and Tien (2013). These authors have uncovered different dynamics of business cycle indicators during "nonrecessionary" phases, which have led them to model the U.S. economy with more than two states. These considerations motivate our focus on recessions.¹⁴

3 Results

Figure 3 plots the estimated dynamic responses to a one standard deviation-shock to uncertainty (here approximated with the VIX) conditional on a linear formulation of the VAR.¹⁵ Unemployment increases significantly and persistently, and follows a hump-

 $^{^{14}}$ Given our focus on recessions, we do not explicitly model the non-recessionary phases. Implicitly, we assume that our results conditional on recessions are not affected by this choice.

¹⁵In the Appendix we show that our results are robust to using alternative indicators of uncertainty like the macro uncertainty factor computed by Jurado, Ludvigson, and Ng (2013) as well as the Corporate Bond Spread considered by Bachmann, Elstner, and Sims (2013).

shaped path before going back to its steady-state value. The reaction of inflation is negative, though it is hardly significant. The policy rate decreases significantly after the shock for a limited number of quarters, following a pattern consistent with a flexible inflation targeting strategy by the Federal Reserve. These results are in line with those obtained by Basu and Bundick (2012) and Leduc and Liu (2013), i.e., our linear model suggests that aggregate uncertainty shocks act as "demand" shocks in the sense that they temporarily open a recession and, to some extent, lower inflation.¹⁶

A quantitatively very different picture emerges when non-linearities are admitted to play a role in this system. Figure 4 superimposes the dynamic responses conditional on a recessionary phase of the economy to those estimated with the linear framework. Several elements are worth noting. First, the reaction of unemployment is much larger during recession. The linear VAR model predicts that an exogenous increase of the VIX may be followed by a reaction of the unemployment rate of about 0.17 percentage points four quarters after the shock, and of about 0.14 percentage points eight quarters after such shock. The non-linear VAR reveals that the same shock, when hitting the economic system during a recession, is estimated to induce an increase of unemployment of 0.36percentage points four quarters after the shock, and 0.41 two years after the shock. The difference is statistically significant. This suggests that uncertainty shocks may exert quite a severe impact on unemployment when the economy is already experiencing a recession. Somewhat not surprisingly (in light of a possible Phillips curve-related reading of U.S. inflation dynamics), the reaction of inflation is also predicted to be larger after the shock. As in the linear case, monetary policy (whose stance is here captured by the federal funds rate) reacts according to a flexible inflation targeting

¹⁶A note of caution on the identification of uncertainty shocks is due here. As stressed by Stock and Watson (2012), uncertainty shocks and liquidity/financial risk shocks are highly correlated, which makes their separate interpretation problematic. Christiano, Motto, and Rostagno (2014) propose a model to interpret the causal role that a measure of risk may play in influencing credit spreads. Following the recent VAR literature, our "uncertainty shocks" are to be interpreted as exogenous variations of an empirical proxy for uncertainty in our VARs.

strategy. Similarly to inflation and unemployment, the federal funds rate is estimated to be more sensitive to uncertainty shocks during recessions.¹⁷

From a modeling standpoint, the non-linear VAR suggests that the relative force of different transmission channels may change over the business cycle. The overall effect on the real side of the economy and inflation is negative during recessions as well as according to the linear model. This evidence is replicable by a model featuring matching frictions in the labor market as shown by Leduc and Liu (2013), who also discuss how price stickings may magnify the demand effects of uncertainty shocks. The quantitative difference found between our two sets of impulse responses may therefore be due to a larger impact exerted by real frictions on the labor market during recessions (e.g., lower likelihood to form a firm-worker match, higher probability of breaking a previously formed-match). Differently, our results cast doubts on pure RBC frameworks featuring a Walrasian labor market. In such models, uncertainty shocks generate expansions due to their effects on labor supply, which raises the level of potential output. Our analysis solidly rejects the prediction of expansionary uncertainty shocks both with linear models and with non-linear frameworks. Hence, our results lend support to the analysis proposed by Basu and Bundick (2012), who show that the introduction of price stickiness in an otherwise standard RBC framework enables their model to replicate the recessionary and deflationary effects of an exogenous increase in uncertainty.

4 Robustness checks

Our exercises suggest that uncertainty shocks are important for the U.S. unemployment dynamics. However, some robustness checks are in order.

¹⁷Admittedly, the differences between the responses based on our linear VAR and those associated to recessions are likely to be over-estimated by the assumption of no change of the recessionary phase we focus on. One should therefore interpret the estimated responses under recessions as an upper bound, more than a mean estimate. On the other hand, the coefficients of our recessions-related VAR are estimated by using also information about the dynamics of the system in the non-recessionary regime, a strategy which is likely to bias the non-linear estimates towards those associated to the linear VAR.

ZLB. First, our results may be due to the Zero-Lower Bound (ZLB) affecting conventional monetary policy moves concerning the nominal interest rate. The Federal Reserve has hit the zero lower bound in December 2008. Since then, it has maintained the fed funds rate at historically low levels. A number of studies have argued that the impact of uncertainty shocks might be substantially more pronounced when the ZLB binds (Basu and Bundick, 2012; Johannsen, 2013). We then run our estimations by considering the sample 1962Q3-2008Q3, which excludes the years of the Great Recession affected by the presence of the ZLB.¹⁸ Figure 5 shows our results. In absence of ZLB, the response of unemployment is weaker and shorter-lived. Its peak response under recessions is equal to 0.30 percentage points and occurs five quarters after the shock vs. a peak equal to 0.42 percentage points occurring six quarters after the shock in the baseline scenario. Consistently, the maximum (in absolute value) reaction of the policy rate in recessions is estimated to be -0.71 percentage points when the observations about the ZLB are included in the sample vs. about -0.92 percentage points when they are excluded. Interestingly, in absence of the ZLB, the path of the unemployment rate suggests a possible "overshoot" some ten quarters after the shock. This evidence points to the possibility of a "wait-and-see" type of behavior by firms in presence of an increase in uncertainty (Bloom, 2009). Our results suggest that the presence of the ZLB may indeed magnify the macroeconomic effects of uncertainty. Hence, our findings lend support to the theoretical predictions put forth by Basu and Bundick (2012) and Johannsen (2013) on the stronger macroeconomic effects of uncertainty shocks in presence of the ZLB.

Alternative indicators of macroeconomic "activity". The variable we look at in our analysis is the unemployment rate. While being of clear interest from a policy-

¹⁸Our results turn out to be virtually unchanged when we consider the sample 1962Q3-2008Q2, which also excludes the bankruptcy of Lehman Brothers, that filed for Chapter 11 bankruptcy protection on September 15, 2008.

making standpoint, this variable is affected by measurement issues due to time-varying labor market participation. Moreover, it has some very low frequency movements. We then experiment with a variety of alternative indicators of macroeconomic "activity". In particular, we rotate series of hours, output, investment, durable consumption, and non-durable consumption in one at a time and estimate four-variate VARs with these alternative series $\mathbf{X}_t^{activity} = [vix_t, \pi_t, activity_t, R_t]'$.¹⁹ Figure 6 displays the responses of our alternative measures of real activity to an uncertainty shock. Clearly, our evidence on a larger impact of uncertainty shocks on real activity extend to all these alternative indicators of the business cycle. Interestingly, our evidence points to a "drop, rebound, and overshoot" effect of uncertainty shocks, which is consistent with a "wait-and-see" optimal behavior in response to an increase in uncertainty (Bloom, 2009).

Omitted variables/Cholesky ordering. Our results may be spurious in presence of misspecification of the econometric model. If our VAR does not embed sufficient information to consistently estimate the uncertainty shocks, the impulse responses could be distorted and, possibly, spuriously magnify the role of such shocks. Variables endowed with relevant information for modeling the shock of interest and/or the interactions among the variables may be omitted from the VAR. Several examples of potentially relevant but omitted variables are provided by the literature. For instance, consumer sentiment may be important for explaining households' decisions and influence labor supply, therefore affecting production and unemployment. VARs may also miss anticipated effects of uncertainty shocks. Christiano, Motto, and Rostagno (2014) show that, in an estimated DSGE model of the business cycle with a number of real, nominal, and financial frictions, anticipated risk (uncertainty) shocks (measured as the

¹⁹We consider hours of all persons of the nonfarm business sector, real GDP, real private nonresidential fixed investment, real personal consumption expenditures – durable goods, and real personal consumption expenditures – nondurable goods plus services. We control for the different degree of integration of these series with respect to the remaining variables in our VAR by considering the former in log-deviations with respect to a cubic trend. Our main finding on larger real effects of uncertainty shocks during recessions is robust to working with these series in growth rates.

evolution of cross-sectional dispersion of firms' capital efficiency) greatly improve their model's descriptive power. This implies that VAR one-step ahead forecast errors of empirical measures of uncertainty may confound unexpected movements of the level of uncertainty with expected ones. Both the first and the second type of informational insufficiency may be tackled by expanding our baseline vector to include possibly omitted variables for better capturing the correlations in the data as well as for modeling agents' expectations over future (and known) realizations of the relevant shocks. Another issue regards our identification strategy, which relies on a Cholesky decomposition conditional on a vector with uncertainty ordered first. Despite being quite popular in the literature, this assumption is debatable. We check the robustness of our results to various perturbations of the baseline vector. Such perturbations are presented and motivated below.

S&P500. Our baseline analysis identifies uncertainty shocks by isolating exogenous movements of the VIX. Such index captures the *volatility* of the stock market. Of course, variations of the *level* of the stock market *per se* may be important determinant of aggregate demand and inflation (for instance, because of financial wealth-related effects in a sticky-price context as in Castelnuovo and Nisticò, 2010). Since in our sample the correlation between the VIX and the log of the S&P500 is 0.28, our baseline model might mix up variations in uncertainty with variations in the level of the stock market index. We then consider the five-variate VAR $\mathbf{X}_t^{S\&P500} = [S\&P500_t, vix_t, \pi_t, un_t, R_t]'$, where "S&P500" captures the log of S\&P500 (source: Federal Reserve Bank of St. Louis' website).²⁰

TFP. Bachmann and Bayer (2013) propose a model in which shocks to firms' prof-

 $^{^{20}}$ The S&P500 displays a distinct up-trending behavior in the sample. We estimate our VAR by employing a cubically detrended measure of (the log of) S&P500. Bloom (2009) and Jurado, Ludvigson, and Ng (2013) Hodrick-Prescott filter the log of the S&P500 index to isolate its cyclical component. Our results are similar when a Hodrick-Prescott filter (smoothing weight: 1,600) is applied to the stock market index.

itability risk, propagated via capital adjustment costs, have the potential to be a major source of business cycle fluctuations. Using a rich German firm-level dataset, they find that such a shock, when taken in isolation, leads firms to adopt a "wait-and-see" strategy for investment. However, the contribution of this shock to the forecast error variance of investment, output, and total hours is found to be limited. Interestingly, the micro-data employed by Bachmann and Bayer (2013) support a version of the model in which aggregate productivity and firm-level risk processes are correlated. In presence of this correlation, shocks to firm's profitability risk explain about one-third of the forecast error variance of output (as well as investment and hours) after ten years. This may be due to the fact that risk shocks today anticipate the future evolution of aggregate productivity, whose systematic impact on output and investment is large. Controlling for movements in TFP is therefore important to isolate the role of uncertainty shocks per se. We then consider the five-variate VAR $\boldsymbol{X}_{t}^{TFP} = [TFP_{t}, vix_{t}, \pi_{t}, un_{t}, R_{t}]'$, where "TFP" is the log of the total factor productivity measure proposed by Fernald (2012). The series we use is adjusted to control for variations in factor utilization as in Basu, Fernald, and Kimball (2006). The source of the data is the Federal Reserve Bank of San Francisco's website.²¹

Consumer sentiment. Uncertainty and consumer confidence also go hand-inhand, and share some information concerning agents' expectations over the future evolution of the economic system. An often employed measure of consumer sentiment is the index of consumer expectations based on information collected via the Michigan Survey of Consumers. The index is calculated as an average of the results coming from three different questions concerning the future evolution of the business cycle (expectations about aggregate business conditions over the next year; expectations about aggregate business conditions over the next five years; expectations about personal financial condi-

 $^{^{21}}$ We use a Hodrick-Prescott filtered measure of the (log of) TFP measure (smoothing weight: 1,600) to preserve the same degree of integration of the other variables in the VAR.

tions over the next year).²² Bachmann and Sims (2012) estimate the systematic effects due to this measure of consumer "confidence" for the transmission of fiscal policy shocks to the business cycle and find it to be substantial, especially during recessions. The correlation between the VIX and this measure of confidence equals -0.29 in our sample. Hence, once may fear that our uncertainty shocks may proxy confidence shocks, rather than representing genuine exogenous variations of uncertainty. We scrutinize this issue by estimating the five-variate VAR $\mathbf{X}_t^{sent} = [sent_t, vix_t, \pi_t, un_t, R_t]'$, where "sent" stands for consumer sentiment.²³

FAVAR. A way to tackle the informational insufficiency issue, popularized by Bernanke, Boivin, and Eliasz (2005), is to add a factor extracted from a large dataset to our VAR, so to purge the (possibly bias-contaminated) estimated shocks. We then consider a large dataset composed of 150 time-series, and extract the common factors which maximize the explained variance of such series (some information on the series of our dataset, their transformations, and the computation of the factors is provided in our Appendix). Our estimation leads us to obtain six common factors, a number equivalent to the one found by Stock and Watson (2012) in their recent analysis on the drivers of the post-WWII U.S. economy. We then conduct a check with the Factor-Augmented Smooth-Transition VAR $\mathbf{X}_t^{favar} = [f_t^1, vix_t, \pi_t, un_t, R_t]'$, where " f_t^1 " is the factor explaining the largest share of variance of the series in our enlarged database.²⁴

Cholesky ordering. Finally, our assumptions to identify an exogenous variation of uncertainty implies that no macroeconomic shock can contemporaneously affect the

²²Information on the Thomson Reuters/University of Michigan Surveys of Consumers can be found at the URL http://www.sca.isr.umich.edu/main.php.

²³Bachmann, Elstner, and Sims (2013) employ a measure of business confidence to control for the role of expectations (first moment). Our results are robust to the use of business confidence (as opposed to consumer confidence).

²⁴Our first factor is just mildly correlated with the unemployment rate (-0.02). Therefore, it is likely not to represent a "redundant" variable in our VAR. Notice that, in line with a Okun's law interpretation of the relationship between real GDP and unemployment, the correlation between the first factor (whose degree of correlation with the real GDP growth rate reads 0.73) and the *difference* in the unemployment rate is much stronger (-0.72).

level of uncertainty in the economic system. While being common in this literature, the assumption is nonetheless questionable. To check the extent to which this assumption may affect our results, we run a set of estimates by ordering uncertainty last in our vector, i.e., $\mathbf{X}_t^{unclast} = [\pi_t, un_t, R_t, vix_t]'$. This alternative ordering allows us to "purge" the VIX by the movements due to past as well as contemporaneous shocks hitting the economic system. By construction, we force the macroeconomic variables modeled with our VAR to have a zero on-impact reaction to uncertainty shocks.

The outcome of all robustness checks are reported in Figure 7. In all cases, we find a recessionary evolution of the unemployment rate comparable to the baseline case. Admittedly, some quantitative effects are present. The vectors featuring either the measure of TFP, the factor, or the measure of consumer confidence predict a somewhat milder response of unemployment with respect to the baseline case. The vector controlling for movements in the S&P500 index returns an even milder (but still quite substantial) short-run response of unemployment. However, as a matter of fact, all scenarios confirm the remarkable increase of unemployment in response to an uncertainty shock. The response of inflation turns out to be quite robust across scenarios, with a clear and abrupt fall in the short-run and a fairly quick rebound. The response of the policy rate is estimated to be extremely robust as well.²⁵

Importantly, the role of non-linearities turns out to be supported also by our sensitivity analysis. Figure 8 shows the difference between the predictions of linear vs. non-linear VARs in each of the cases previously shown in Figure 7. In particular, it focuses on the two policy-relevant variables in our analysis, i.e., unemployment and

 $^{^{25}}$ Bachmann and Bayer (2013) show that most of the relevance of firm-level risk shocks is due to their systematic interaction with aggregate productivity. Our results are confirmed by an exercise in which the systematic impact of uncertainty shocks on TFP is set to zero in the VAR. Admittedly, the discrepancy between our results and Bachmann and Bayer's (2013) may be due to the inability of our VAR to correctly capture the "structural" correlation between risk and aggregate productivity. Moreover, our measure of *aggregate* uncertainty differs from Bachmann and Bayer's, which is constructed with a detailed dataset referring to German firms. We leave the exploration of the relationships among firm risk, aggregate uncertainty, and aggregate productivity to future research.

inflation. While some heterogeneity across scenarios may be detected, all cases under scrutiny point to a substantially deeper recession and deflationary phase after a shock when non-linearities are taken into account, and recessions are the focus of our investigation. Quantitatively, the indications coming from the VARs are very similar.²⁶

Conditionally-linear IRFs. As in Auerbach and Gorodnichenko (2012), the computation of our IRFs is undertaken by assuming to remain in a recessionary state after the uncertainty shock has hit the economic system. Ramey and Zubairy (2013) criticize Auerbach and Gorodnichenko's (2012) computation of the macroeconomic IRFs to a positive fiscal spending shock. An expansionary shock, their argument goes, is likely to help the economy out of a recession. Hence, the omission of the possibility of switching from a regime to another could be a source of bias. We believe that Ramey and Zubairy's (2013) critique hardly applies to our case. Our analysis quantifies the effects of a contractionary shock such as an exogenous increase in uncertainty on unemployment in recessions. Hence, our assumption of remaining in the same phase of the business cycle after the shock is somewhat natural. It also enables us to enjoy a computational benefit, since it simplifies the calculation of IRFs and makes them independent with respect to sign, size and history of the shocks. We conducted an experiment (not documented here for the sake of brevity, but shown in the Appendix) and computed Generalized IRFs that account for the feedback going from the evolution of our transition variable (included in our set of endogenous variables in this experiment) to the probability of recession. Our main result, that the real effects of uncertainty shocks are larger in recessions, turns out to be fully confirmed by this experiment.

²⁶Our results are also robust to the inclusion of oil prices in the vector.

5 FEVDs

Finally, we assess the contribution of uncertainty shocks for the dynamics of the variables of interest by performing a forecast error variance decomposition. Table 1 collects figures concerning our eight quarter-ahead investigation. Conditional on the linear VAR, uncertainty shocks are estimated to be responsible for an important share of the variance of unemployment (23%), but negligible for inflation (1%) and the policy rate (2%). Quite differently, conditional on recessions uncertainty shocks contribute three times as much to the variance of unemployment (62%), and explain a substantial chunk of the variance of the policy rate (41%). The contribution of inflation is also much larger (8%) than estimated with a linear model.

To appreciate the role of uncertainty shocks, Table 1 also reports the estimated contribution of monetary policy shocks, which are identified with a standard Cholesky scheme. The linear model suggests a large contribution to the variance of the policy rate (49%), and a moderate one as for unemployment (5%) and inflation (1%). The nonlinear model predicts a milder contribution of policy shocks on unemployment (1%). Some lessons can be drawn from this variance decomposition analysis. First, uncertainty shocks importantly contribute to the dynamics of unemployment in recessions. Second, linear models may lead to an underestimation of the contribution of uncertainty shocks, a finding in line with our impulse response function analysis. Third, uncertainty shocks turn out to be more important than monetary policy shocks in explaining the dynamics of unemployment. Incidentally, we notice that monetary policy shocks are estimated to be more powerful (as for their effects on unemployment) in "normal times" (here approximated by our linear model, which mixes up recessions and non-recessionary phases) than during recessions. This finding lines up with the recent analysis by Vavra (2014). He studies price-setting models with volatility shocks, and shows that greater volatility leads to an increase in aggregate price flexibility. Consequently, a nominal stimulus mostly generates inflation rather than output growth. Since volatility is countercyclical, this implies that monetary stimulus has smaller real effects during recessions. Vavra (2014) shows that his models matches a variety of facts in CPI micro data that standard price-setting models miss. Empirical support to the prediction of policy shocks being less important for the dynamics of the real side of the economy when uncertainty is high is also offered by Aastveit, Natvik, and Sola (2013) and Pellegrino (2014), who work with non-linear VARs and macroeconomic data for a number of countries, including the United States.

One potential issue to take into account is that the estimated contribution of uncertainty shocks to the variance of the forecast error of unemployment might be biased due to the lack of relevant information in our baseline VAR. We then implement the same exercise with our five-variate model with S&P500. Table 2 collects the contribution of uncertainty shocks conditional on this enriched model, and contrast them to those shown in Table 1. Perhaps not surprisingly, the five-variate VAR suggests a substantially lower contribution of uncertainty shocks during recessions (10%). However, the non-linear model confirms, once again, a much more important role for uncertainty shocks than what suggested by a standard linear VAR (2%).²⁷

6 Conclusions

We investigate the macroeconomic effects of uncertainty shocks in the post-WWII U.S. economy with linear and non-linear (Smooth-Transition) VARs. We find such effects to be asymmetric over the business cycle. In particular, the response of unemployment conditional on recessions is documented to be substantially larger than the one pre-

 $^{^{27}}$ The same exercise conducted with our FAVAR model returns qualitatively similar results. In particular, uncertainty shocks are estimated to exert a very mild contribution to the forecast error variances of inflation and the policy rate (1%), and a moderate contribution to unemployment rate's forecast error variance (10%). Differently, the figures under recessions read 6% (inflation), 26% (unemployment rate), and 31% (policy rate).

dicted by a linear VAR model. We also find a stronger reactiveness of inflation during economic downturns. Such differences are shown to be robust to a variety of perturbations of our baseline vector, including different information sets, alternative measures of uncertainty, and different strategies to identify uncertainty shocks in the VARs. We conclude that linear models mixing up recessions and non-recessionary phases may substantially downplay the effects triggered by uncertainty shocks.

From a modeling standpoint, our results support the modeling of sticky prices, which have been shown to help micro-founded DSGE models to replicate the comovements involving output and its components conditional on an uncertainty shock (Basu and Bundick, 2012). Moreover, our results lend support to the modeling of real frictions on the labor market, which have been shown to be key for replicating the response of unemployment to uncertainty hikes, above all when combined with nominal price frictions (Leduc and Liu, 2013). Finally, we find evidence in favor of a stronger effect of uncertainty shocks in presence of the zero-lower bound, a prediction in line with the theoretical investigations by Basu and Bundick (2012) and Johannsen (2013).

Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). Gray areas: 68% bootstrapped confidence bands. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

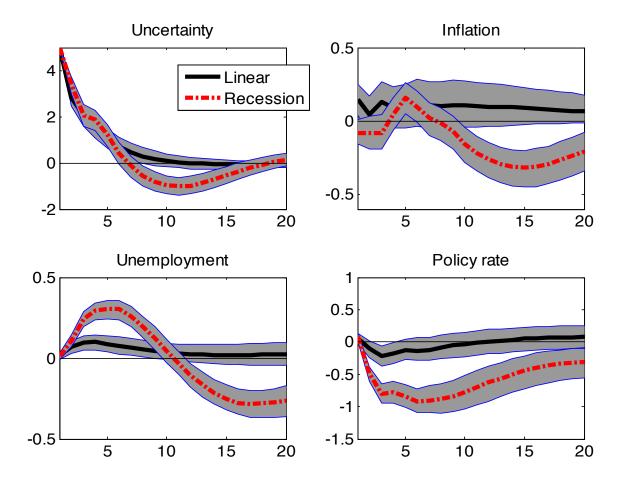

Figure 5: Macroeconomic effects of uncertainty in recessions: Pre Zero-Lower Bound sample. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2008Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). Gray areas: 68% bootstrapped confidence bands. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

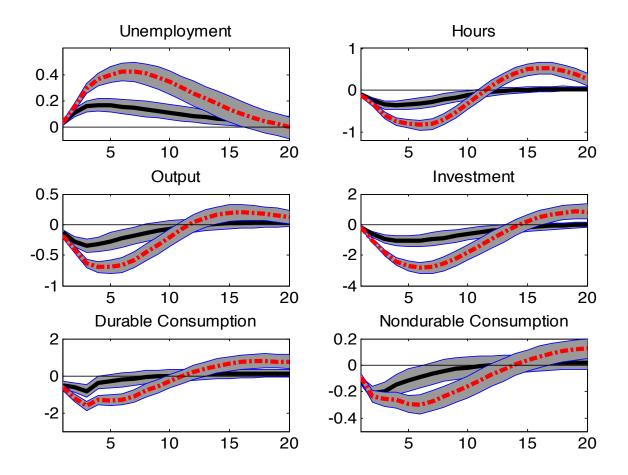

Figure 6: Macroeconomic effects of uncertainty in recessions: Real activity indicators. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. VARs with four variables (uncertainty, inflation, indicator of real activity, policy rate). Gray areas: 68% boostrapped confidence bands. Indicators of real activity considered in log-deviations with respect to a cubic trend. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

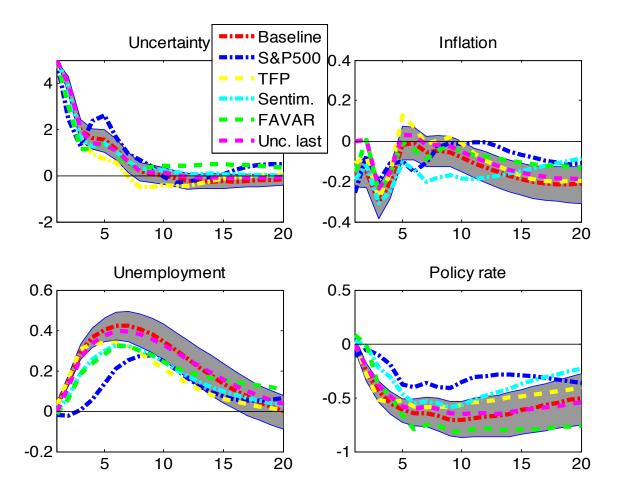

Figure 7: Macroeconomic effects of uncertainty in recessions: Robustness checks. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). S&P500: quartely observations of the (cubically detrended) log of the S&P500 index placed on top of the baseline VAR. TFP: VAR with the utilization adjusted-(log)series of TFP à la Fernald (2012) (cyclical component as isolated by the Hodrick-Prescott filter, smoothing weight: 1,600) on top of the variables in the baseline vector. Cons. Sent.: VAR featuring the Consumer Sentiment from the Michigan Survey placed on top of the baseline VAR. TAR: VAR with a common factor extracted from 150 U.S. time series placed on top of the baseline VAR. Uncert. last: Uncertainty placed last in the otherwise baseline VAR. Gray areas: 68% boostrapped confidence bands, baseline estimates. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

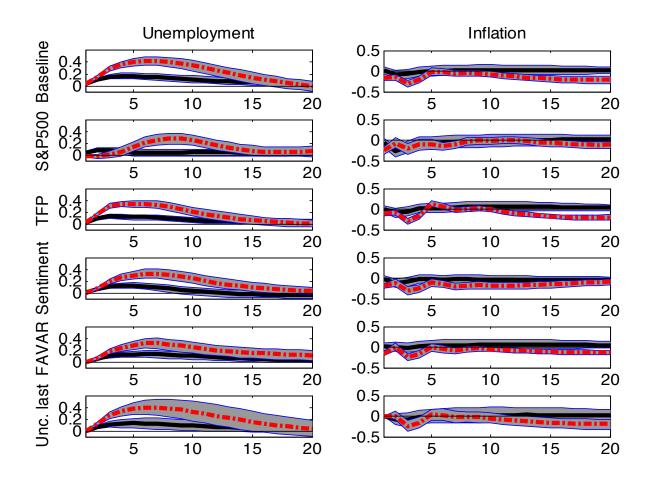

Figure 8: Robustness checks: Omitted variables/alternative orderings. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). S&P500: quartely observations of the (cubically detrended) log of the S&P500 index placed on top of the baseline VAR. TFP: VAR with the HP-filtered utilization adjusted-(log)series of TFP à la Fernald (2012) on top of the variables in the baseline vector. Cons. Sent.: VAR featuring the Consumer Sentiment from the Michigan Survey placed on top of the baseline VAR. FAVAR: VAR with a common factor extracted from 150 U.S. time series placed on top of the baseline VAR. Gray areas: 68% bootstrapped confidence bands surrounding our baseline estimates. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

Appendix of "Uncertainty Shocks and Unemployment Dynamics: An Analysis of Post-WWII U.S. Recessions" by Giovanni Caggiano, Efrem Castelnuovo, Nicolas Groshenny

This Appendix documents statistical evidence in favor of a non-linear relationship between unemployment and uncertainty. It also offers some details on the estimation of our non-linear VARs, as well as on the computation of the factors employed to estimate the FAVAR. Finally, it reports some extra-results, which have not been included in the paper for the sake of brevity.

Statistical evidence in favor of non-linearities

We begin our empirical analysis with a simple univariate autoregressive model for the unemployment rate, which we augment to take into account the possible non-linear role of uncertainty (proxied by the VIX index). The model is the following:

$$u_t = c + \sum_{i=1}^k \left(\beta_{u,i} u_{t-i} + \beta_{vix,i} vix_{t-i} + \beta_{u_vix,i} u_{t-i} vix_{t-i} \right) + \varepsilon_t.$$

We estimate it with U.S. quarterly data on unemployment and uncertainty spanning the period 1962Q3-2012Q3 (a detailed description of the data is provided in the paper). The model is endowed with two lags for each regressor, and estimated by Ordinary-Least Squares. Our point estimates, along with the White heteroskedasticity-consistent standard errors, are displayed below:¹

$$u_{t} = \underbrace{0.149}_{(0.098)} + \underbrace{1.414u_{t-1}}_{(0.079)} - \underbrace{0.457u_{t-2}}_{(0.073)} + \underbrace{0.008vix_{t-1}}_{(0.004)} - \underbrace{0.002vix_{t-2}}_{(0.004)} + \underbrace{0.006u_{t-2}vix_{t-2}}_{t-2} + \widehat{\varepsilon}_{t}.$$

As shown by Luukkonen, Saikkonen, and Teräsvirta (1988), if the coefficients of the interaction terms $\beta_{u_vix,1}$ and $\beta_{u_vix,2}$ are non-zero, the assumption of linearity in the relationship between unemployment and uncertainty is rejected by the data (see also

¹The absence of serial correlation of the estimated residual cannot be rejected by the Breusch-Godfrey Lagrange Multiplier test, which delivers a p-value associated to the asymptotic χ^2 distribution equal to 0.90 (with two lags of the residuals used in the regression conducted for testing purposes). Consequently, the results obtained with a Newey-West heteroskedasticity-consistent correction of the standard errors are virtually the same as those presented in the paper.

Tsay, 1986). The p-value of a F-test for the null hypothesis $H_0: \beta_{u_vix,1} = \beta_{u_vix,2} = 0$ equals 0.003, which is a clear rejection of the assumption of linearity.

To detect non-linear dynamics at a multivariate level, we apply the test proposed by Teräsvirta and Yang (2013). Their framework is particularly well suited for our analysis since it is a test of the null hypothesis of linearity versus a specified nonlinear alternative, that of a (Vector Logistic) Smooth Transition Vector AutoRegression with a single transition variable.

Consider the following p-dimensional 2-regime approximate logistic STVAR model:

$$\mathbf{X}_t = \mathbf{\Theta}_0' \mathbf{Y}_t + \mathbf{\Theta}_1' \mathbf{Y}_t z_t + oldsymbol{arepsilon}_t$$

where $\mathbf{X}_t = [vix_t, \pi_t, u_t, R_t]'$ is the $(p \times 1)$ vector of endogenous variables, vix_t is the VIX index, π_t is inflation, u_t is the unemployment rate, R_t is a policy rate, $\mathbf{Y}_t = [\mathbf{X}_{t-1}| \dots |\mathbf{X}_{t-k}| \boldsymbol{\alpha}]$ is the $((k \times p + q) \times 1)$ vector of exogenous variables (including endogenous variables lagged k times and a column vector of constants $\boldsymbol{\alpha}$), z_t is the transition variable, and Θ_0 and Θ_1 are matrices of parameters. In our case, the number of endogenous variables is p = 4, the number of exogenous variables is q = 1 and the number of lags is k = 1 (this is due to the 'curse of dimensionality', as indicated in Teräsvirta and Yang, 2012). Under the null hypothesis of linearity, $\Theta_1 = \mathbf{0}$.

The Teräsvirta-Yang test for linearity versus the STVAR model can be performed as follows:

- 1. Estimate the restricted model ($\Theta_1 = 0$) by regressing \mathbf{X}_t on \mathbf{Y}_t . Collect the residuals $\tilde{\mathbf{E}}$ and the matrix residual sum of squares $\mathbf{RSS}_0 = \tilde{\mathbf{E}}'\tilde{\mathbf{E}}$.
- 2. Run an auxiliary regression of $\tilde{\mathbf{E}}$ on $(\mathbf{Y}_t, \mathbf{Z}_1)$ where $\mathbf{Z}_1 = [\mathbf{X}'_t z_t]$. Collect the residuals $\tilde{\boldsymbol{\Xi}}$ and compute the matrix residual sum of squares $\mathbf{RSS}_1 = \tilde{\boldsymbol{\Xi}}' \tilde{\boldsymbol{\Xi}}$.
- 3. Compute the test-statistic

$$LM = Ttr \left\{ \mathbf{RSS}_0^{-1} \left(\mathbf{RSS}_0 - \mathbf{RSS}_1 \right) \right\}$$
$$= T \left(p - tr \left\{ \mathbf{RSS}_0^{-1} \mathbf{RSS}_1 \right\} \right)$$

where $tr \{\cdot\}$ denotes the trace of a matrix. Under the null hypothesis, the test statistic is distributed as a χ^2 with p(kp+q) degrees of freedom (in our case, 20 degrees of freedom). For our model, we get LM = 34.52, corresponding to a p-value of 0.0228. Hence, we reject the null hypothesis of linearity at conventional confidence levels.

Estimation of the non-linear VARs

Our model (1)-(4) is estimated via maximum likelihood.² The model's log-likelihood reads as follows:

$$\log L = const + \frac{1}{2} \sum_{t=1}^{T} \log |\boldsymbol{\Omega}_t| - \frac{1}{2} \sum_{t=1}^{T} \boldsymbol{u}_t' \boldsymbol{\Omega}_t^{-1} \boldsymbol{u}_t$$
(A1)

where $\boldsymbol{u}_t = \boldsymbol{X}_t - (1 - F(z_{t-1}))\boldsymbol{\Pi}_{NR}\boldsymbol{X}_{t-1} - F(z_{t-1})\boldsymbol{\Pi}_R\boldsymbol{X}_{t-1}$ is the vector or residuals. Our goal is to estimate the parameters $\boldsymbol{\Psi} = \{\gamma, \boldsymbol{\Omega}_R, \boldsymbol{\Omega}_{NR}, \boldsymbol{\Pi}_R(L), \boldsymbol{\Pi}_{NR}(L)\}$, where $\boldsymbol{\Pi}_j(L) = [\boldsymbol{\Pi}_{j,1} \dots \boldsymbol{\Pi}_{j,p}], j \in \{R, NR\}$. The high-non linearity of the model and its many parameters render its estimation with standard optimization routines problematic. Following Auerbach and Gorodnichenko (2012), we employ the procedure described below.

Conditional on $\{\gamma, \Omega_R, \Omega_{NR}\}$, the model is linear in $\{\Pi_R(L), \Pi_{NR}(L)\}$. Then, for a given guess on $\{\gamma, \Omega_R, \Omega_{NR}\}$, the coefficients $\{\Pi_R(L), \Pi_{NR}(L)\}$ can be estimated by minimizing $\frac{1}{2} \sum_{t=1}^{T} \boldsymbol{u}_t' \Omega_t^{-1} \boldsymbol{u}_t$. This can be seen by re-writing the regressors as follows. Let $\boldsymbol{W}_t = \begin{bmatrix} F(z_{t-1})\boldsymbol{X}_{t-1} & (1 - F(z_{t-1}))\boldsymbol{X}_{t-1} & \dots & F(z_{t-1})\boldsymbol{X}_{t-p} & (1 - F(z_{t-1}))\boldsymbol{X}_{t-p} \end{bmatrix}$ be the extended vector of regressors, and $\boldsymbol{\Pi} = \begin{bmatrix} \Pi_R(L) & \Pi_{NR}(L) \end{bmatrix}$. Then, we can write $\boldsymbol{u}_t = \boldsymbol{X}_t - \boldsymbol{\Pi} \boldsymbol{W}_t'$. Consequently, the objective function becomes

$$\frac{1}{2} \sum_{t=1}^{T} (\boldsymbol{X}_t - \boldsymbol{\Pi} \boldsymbol{W}_t')' \boldsymbol{\Omega}_t^{-1} (\boldsymbol{X}_t - \boldsymbol{\Pi} \boldsymbol{W}_t').$$

It can be shown that the first order condition with respect to Π is

$$vec\mathbf{\Pi}' = \left(\sum_{t=1}^{T} \left[\mathbf{\Omega}_{t}^{-1} \otimes \mathbf{W}_{t}' \mathbf{W}_{t}\right]\right)^{-1} vec\left(\sum_{t=1}^{T} \mathbf{W}_{t}' \mathbf{X}_{t} \mathbf{\Omega}_{t}^{-1}\right).$$
(A2)

This procedure iterates over different sets of values for $\{\gamma, \Omega_R, \Omega_{NR}\}$. For each set of values, Π is obtained and the logL (A1) computed.

Given that the model is highly non-linear in its parameters, several local optima might be present. Hence, it is recommended to try different starting values for $\{\gamma, \Omega_R, \Omega_{NR}\}$. To ensure positive definiteness of the matrices Ω_R and Ω_{NR} , we focus on the alternative vector of parameters $\Psi = \{\gamma, chol(\Omega_R), chol(\Omega_{NR}), \Pi_R(L), \Pi_{NR}(L)\}$, where *chol* denotes a Cholesky decomposition.

The construction of confidence intervals for the parameter estimates as well as the impulse responses is complicated by, once again, the non-linear structure of the problem. We compute them by appealing to a Markov Chain Monte Carlo (MCMC) algorithm

 $^{^2{\}rm This}$ Section heavily draws on Auerbach and Gorodnichenko's (2012) "Appendix: Estimation Procedure".

developed by Chernozhukov and Hong (2003) (CH hereafter). This method delivers a global optimum. Then, we compute confidence intervals for our IRFs with a standard bootstrapping algorithm.

Following CH, the estimation of the model is implemented via a Metropolis-Hastings algorithm. Given a starting value $\Psi^{(0)}$, the procedure constructs chains of length N of the parameters of our model following these steps:

Step 1. Draw a candidate vector of parameter values $\Theta^{(n)} = \Psi^{(n)} + \psi^{(n)}$ for the chain's n + 1 state, where $\Psi^{(n)}$ is the current state, $\psi^{(n)}$ is a vector of i.i.d. shocks drawn from $N(0, \Omega_{\Psi})$, and Ω_{Ψ} is a diagonal matrix.

Step 2. Set the n + 1 state of the chain $\Psi^{(n+1)} = \Theta^{(n)}$ with probability equal to $\min\left\{1, L(\Theta^{(n)})/L(\Psi^{(n)})\right\}$, where $L(\Theta^{(n)})$ is the value of the likelihood function conditional on the candidate vector of parameter values, and $L(\Psi^{(n)})$ the value of the likelihood function conditional on the current state of the chain. Otherwise, set $\Psi^{(n+1)} = \Psi^{(n)}$.

The starting value $\Theta^{(0)}$ is computed by working with a second-order Taylor approximation of the model (1)-(4), so that the model can be written as a regression of X_t on lags of X_t , $X_t z_t$, and $X_t z_t^2$. The residuals from this regression are employed to fit the expression for the reduced-form time-varying variance-covariance matrix of the VAR (see our paper) using maximum likelihood to estimate Ω_R and Ω_{NR} . Conditional on these estimates and given a calibration for γ , we can construct Ω_t . Conditional on Ω_t , we can get starting values for $\Pi_R(L)$ and $\Pi_{NR}(L)$ via equation (A2).

The initial (diagonal matrix) Ω_{Ψ} is calibrated to one percent of the parameter values. It is then adjusted "on the fly" for the first 20,000 draws to generate an acceptance rate close to 0.3, a typical choice for this kind of simulations (Canova (2007)). We employ N = 50,000 draws for our estimates, and retain the last 20% for inference.

N = 50,000 draws for our estimates, and retain the last 20% for inference. As shown by CH, $\overline{\Psi} = \frac{1}{N} \sum_{n=1}^{N} \Psi^{(n)}$ is a consistent estimate of Ψ under standard regularity assumptions on maximum likelihood estimators. Then, we compute the 68% confidence bands of our IRFs via a standard bootstrapping algorithm based on 500 repetitions. Our impulse responses are conditional on an uncertainty shock of size $\overline{\sigma} = 5$, which is the size of the standard deviation of the uncertainty shock in the linear model.

Computation of the factors for the FAVAR approach

We follow Stock and Watson (2012) to estimate the factors from a large unbalanced data set of US variables. Let $\mathbf{X}_t = (X_{1t}, \ldots, X_{nt})'$ denote a vector of n macroeconomic time series, with $t = 1, \ldots, T$. X_{it} is a single time series transformed to be stationary and to have mean zero. The dynamic factor model expresses each of the n time series as the sum of a common component driven by r unobserved factors \mathbf{F}_t plus an idiosyncratic disturbance term e_{it} :

$$\mathbf{X}_t = \mathbf{\Lambda} \mathbf{F}_t + \mathbf{e}_t \tag{A3}$$

where $\mathbf{e}_t = (e_{1t}, \ldots, e_{nt})'$ and $\mathbf{\Lambda}$ is the $n \times r$ matrix of factor loadings.

The factors are assumed to follow a linear and stationary vector autoregression:

$$\boldsymbol{\Phi}\left(L\right)\boldsymbol{F}_{t} = \boldsymbol{\eta}_{t} \tag{A4}$$

where $\Phi(L)$ is a $r \times r$ matrix of lag polynomials with the vector of r innovations η_t . Stationarity implies that $\Phi(L)$ can be inverted and F_t has the moving average representation:

$$\boldsymbol{F}_{t} = \boldsymbol{\Phi}\left(L\right)^{-1} \boldsymbol{\eta}_{t}.$$
 (A5)

With n large, under the assumption that there is a single-factor structure, simple cross-sectional averaging provides an estimate of \mathbf{F}_t good enough to treat $\hat{\mathbf{F}}_t$ as data in a regression without a generated regressor problem. With multiple factors, Stock and Watson (2002) show that a consistent estimate of \mathbf{F}_t is obtained using principal components.

Our data set is standard in the recent literature on factor models (see ? and Stock and Watson, 2012). It contains an unbalanced panel of 150 quarterly series, with starting date 1947Q1 and end date 2012Q3. The data are grouped into 12 categories: NIPA variables (31); industrial production (16); employment and unemployment (14); housing starts (6); inventories, orders and sales (12); prices (15); earnings and productivity (13); interest rates (10); money and credit (12); stock prices (5); exchange rates (7); and other (9). Earnings and productivity data include TFP-adjusted measures of capacity utilization introduced by Basu, Fernald, and Kimball (2006). The category labeled "other" includes expectations variables.

All series were transformed to be stationary with zero mean (see Table A1 for details). The factors were estimated using principal components as in Stock and Watson (2012). The assumption that the factors can be estimated with no breaks over the period 1947Q2-2012Q3 is motivated by the findings of Stock and Watson (2002), who show that the space spanned by the factors can be estimated consistently even if there is instability in Λ .

Data, transition probabilities, and further robustness checks

We provide additional evidence on the data and the transition probabilities employed in our analysis, as well as about the results obtained in several other robustness checks, not reported in the paper for the sake of brevity.

Data. Figure A1 plots the four time-series we model in our baseline analysis.

Transition probability – different calibrations for the slope parameter. Figure A2 depicts the transition probability obtained by calibrating $\gamma = 1.5$ as in Auerbach and Gorodnichenko (2012), Bachmann and Sims (2012), and Berger and Vavra (2014), as well as that used in the paper, i.e. $\gamma = 1.75$ chosen to match the frequency of recessions as dated by the NBER in our sample (17%). As shown in Figure 2, the transition probability used in our analysis overlaps that employed in Auerbach and Gorodnichenko (2012), Bachmann and Sims (2012), and Berger and Vavra (2014) almost perfectly.

Alternative measures of economic activity – growth rates. In the paper we show that our results are robust to the employment of several indicators of economic activity such as hours, output, investment, durable consumption, and non-durable consumption. We consider variables in growth rates to control for the possibly different degree of integration relative to that of the remaining variables included in the baseline VAR. Figure A3 plots the responses obtained by estimating four-variate VARs including the growth rate of these alternative measures of real activity. Our main finding, that the real effect of uncertainty shocks is larger during recessions, turns out to be robust to growth rates, but it is less evident when consumption is considered, particularly as far as non-durable consumption is concerned. This exception is perhaps not surprising, because of the lower, if any, adjustment costs consumers face when deciding whether to buy a non-durable consumption good (as opposed to a durable one) or not. On the role of "wait-and-see" strategies implemented in presence of adjustment costs and higher uncertainty, see Bloom (2009). Interestingly, while observing a clear drop in all measures of economic activities, the "rebound" documented in the paper when dealing with cubically-detrended variables is not present here. We postpone an analysis of the robustness of Bloom's (2009) VAR results to different data transformation to future research.

Generalized Impulse Response Functions. Our baseline results are obtained by assuming that the economy remains in a recessionary state for twenty quarters after the shock. We check the robustness of this assumption by computing Generalized IRFs (GIRFs). GIRFs account for the feedback going from the evolution of our transition variable (included in our set of endogenous variables in this experiment) to the probability of being in a recession. Our main result, i.e., larger effects of uncertainty shocks in recessions, turns out to be fully confirmed by this experiment. Our GIRFs are shown in Figure A4.

Calibration of the slope parameter. Our baseline results are conditional on the calibration for $\gamma = 1.75$. Results are robust to alternative calibrations for γ implying a frequency of recessions ranging from 10% ($\gamma = 2.4$) to 25% ($\gamma = 1.2$), where the lower bound is determined by the minimum amount of observations each regime should contain according to Hansen (1999). Figures A5 and A6 show the impulse responses for these two alternative scenarios.

Different measures of uncertainty. So far, the analysis has hinged upon the VIX as a proxy of the macroeconomic uncertainty affecting the economic system. As discussed in Section 2, alternative proxies for uncertainty have been proposed in the literature. Jurado, Ludvigson, and Ng (2013) compute a macro uncertainty factor by modeling the common component of n-step ahead forecast error variances of 132 macro-economic series.³ Bachmann, Elstner, and Sims (2013) consider the Corporate Bond Spread (computed as the difference between the Baa 30 year-yield and the Treasury yield at a comparable maturity). We re-run our estimates by replacing the VIX with these two measures of uncertainty (employed one at a time). As in the baseline scenario, we consider the effects of one standard deviation innovation to uncertainty.

Figure A7 compares the baseline results with those obtained with these two alternative measures of uncertainty. The responses are somewhat different from a quantitative standpoint, a fact that confirms the different information content carried by these indicators of uncertainty. In particular, the response of inflation to the Corporate Bond spread is estimated to be stronger relative to the baseline scenario, while that of unemployment slightly weaker. The reaction of unemployment to unexpected movements in

³Jurado, Ludvigson, and Ng (2013) use the method of diffusion index forecast (a forecasting model with predictors that span a rich information set) to compute the forecast errors of the 132 macroeconomic series of interest, and employ a stochastic volatility model to compute the variance of such forecast errors. As a measure of macro uncertainty, we take the common factor they computed conditional on the one year-ahead forecast error variances. The factors computed by Jurado, Ludvigson, and Ng (2013) with the large dataset of macro series are monthly. We create quarterly observations by taking within-quarter averages.

the common factor computed by Jurado, Ludvigson, and Ng (2013) is quite similar to our baseline result. From a qualitative standpoint, all three indicators of uncertainty point to the same evidence, i.e., uncertainty hikes open a persistent recession and a deflation, therefore acting as a demand shock. In this sense, our non-linear analysis offers solid support to the prediction by Leduc and Liu (2013) on the effects of uncertainty on unemployment.

Monthly data. Given the high number of parameters to estimate, our non-linear VAR model is very demanding on the data. We then augment the degrees of freedom of our empirical exercise by moving to monthly data. This move enables us to enjoy an additional benefit, i.e., our recursive identifying restriction becomes more plausible. Because of data availability, we consider CPI inflation (instead of GDP inflation) and work with a transition indicator constructed by using a twelve-terms moving average of the growth rate of industrial production. We then recalibrate our slope parameter $\gamma = 1.8$ so to replicate the frequency of recessions in our sample conditional on this different transition indicator. Figure A8 contrasts our probability of being in a recession with the NBER recessions at monthly frequencies. Our transition probability tracks well the NBER recessions in the sample under investigation, which is 1962M7-2012M9. Figure A9 plots our responses conditional on monthly data. Again, the response of unemployment is estimated to be larger than the one predicted by a linear framework.

Table A1 (continued). **Time series employed for the computation of the factors**. Classification of the series: 1-31: "NIPA"; 32-47: "Industrial Production"; 48-61: "Employment and Unemployment"; 62-67: "Housing Starts"; 68-79: "Inventories", "Orders and Sales"; 80-94: "Prices"; 95-107: "Earnings and Productivity"; 108-117: "Interest Rates"; 118-129: "Money and Credit"; 130-134: "Stock Prices"; 135-141: "Exchange Rates"; 142-150: "Others". The column labeled "Tr." indicates the transformation applied to the series (1 = level, 2 = first difference, 3 = logarithm, 4 = second difference, 5 = first difference of logarithm, 6 = second difference of logarithm). Data source: Federal Reserve Bank of St. Louis' website.

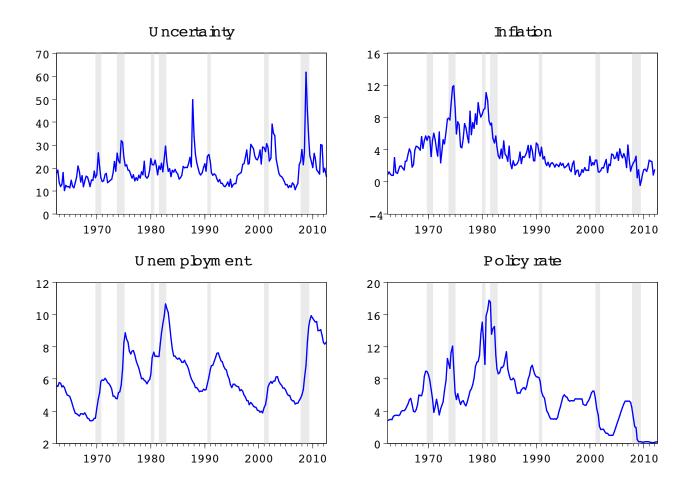

Figure A1 - Macroeconomic variables. Sample: 1962Q3-2012Q3. Uncertainty measured with the VIX as in Bloom (2009). Inflation measured as the annualized quarter-on-quarter growth rate of the implicit GDP deflator. Unemployment is the Civilian Unemployment rate. Policy rate is the Federal Funds Rate.

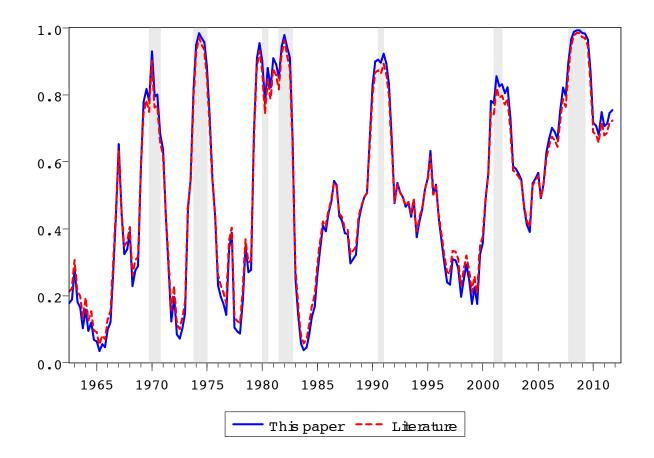

Figure A2 - Probability of being in a recessionary phase. Blue solid line: Transition function F(z) as in this paper, which is conditional on a slope parameter = 1.75. Red dotted line: Transition function F(z) as in Auerbach and Gorodnichenko (2012), Bachmann and Sims (2012), and Berger and Vavra (2014), which is conditional on a slope parameter = 1.5. Shaded columns: NBER recessions.

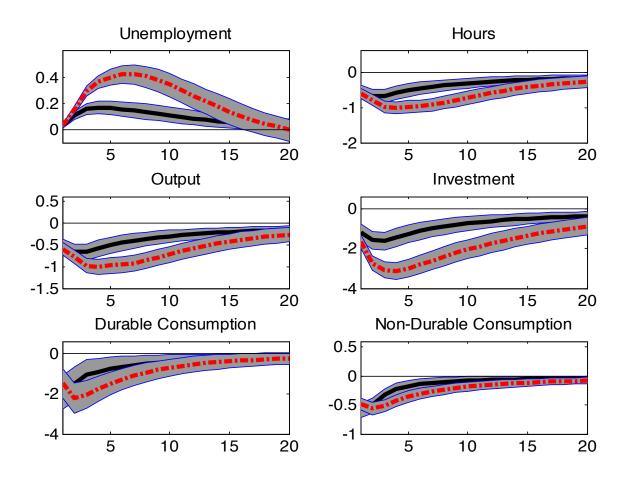

Figure A3 - Macroeconomic effects of uncertainty in recessions: Real activity indicators. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. VARs with four variables (uncertainty, inflation, indicator of real activity, policy rate). Gray areas: 68% bootstrapped confidence bands. Indicators of real activity considered in cumulated growth rates (average values). Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

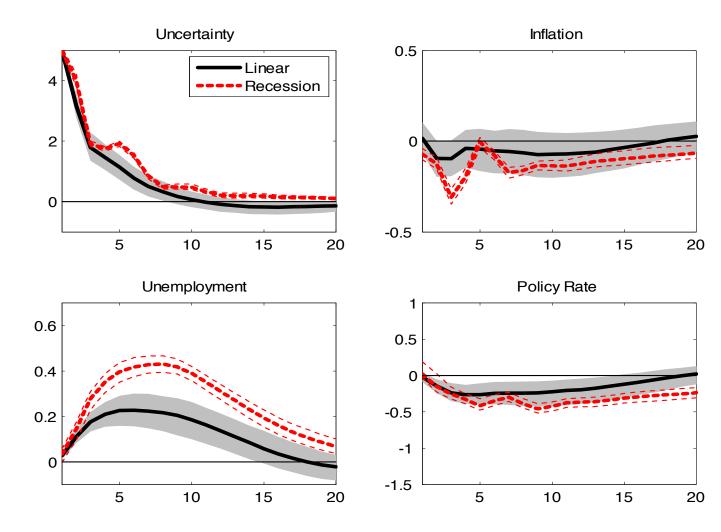

Figure A4 - Generalized Impulse Response Functions to an uncertainty shock. Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). Gray areas: 68% bootstrapped confidence bands. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals. Generalized Impulse Responses computed by accounting for the feedback going from the (responses of the) variables modeled in the vector to the probability of staying in a recessionary-phase as in Koop, Pesaran, and Potter (1996). Vector to compute the GIRFs estimated by considering the transition indicator z (standardized backward-looking moving average (seven terms) of the real GDP growth rate) as first variable (labeled as "output" in the Figure) in the vector.

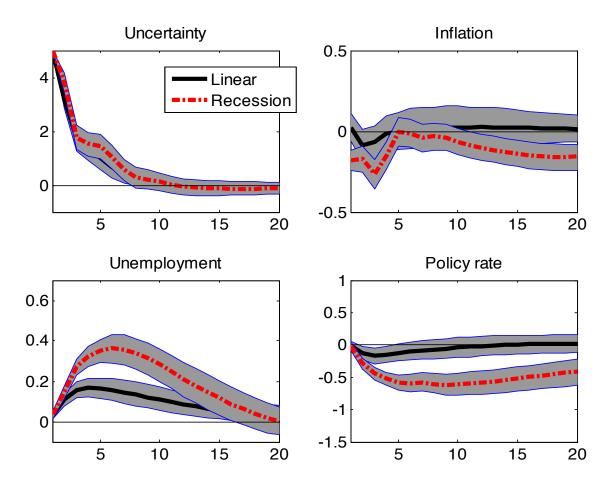

Figure A5 - Macroeconomic effects of uncertainty in recessions: High gamma. Slope parameter gamma set to 2.4, a value implying a frequency of recessions in the sample equal to 10% (conditional on our transition indicator). Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). Gray areas: 68% bootstrapped confidence bands. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

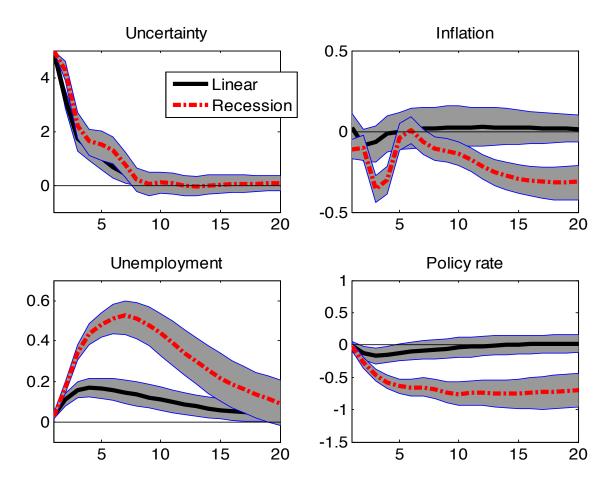

Figure A6 - Macroeconomic effects of uncertainty in recessions: Low gamma. Slope parameter gamma set to 1.2, a value implying a frequency of recessions in the sample equal to 25% (conditional on our transition indicator). Effects of a one standard deviation shock to VIX. Sample: 1962Q3-2012Q3. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, inflation, unemployment, policy rate). Gray areas: 90% confidence sets. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.

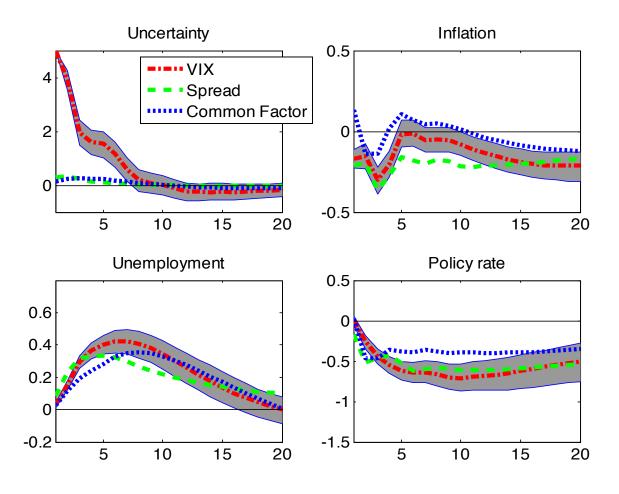

Figure A7 - Impact of uncertainty measures: Comparison. Effects of a one standard deviation shock to each uncertainty indicator. Note: VIX and (Corporate Bond) Spread, sample: 1962Q3-2012Q3. Common Factor: Common factor of the one year-ahead forecast error variance of a large number of time-series computed by Jurado, Ludvigson, and Ng (2013). Quarterly realizations computed as within-quarter averages of monthly estimates. Gray areas: 68% bootstrapped confidence bands. Note: Sample of the Forec. Error Common Factor analysis: 1962Q3-2011Q4 (due to data availability).

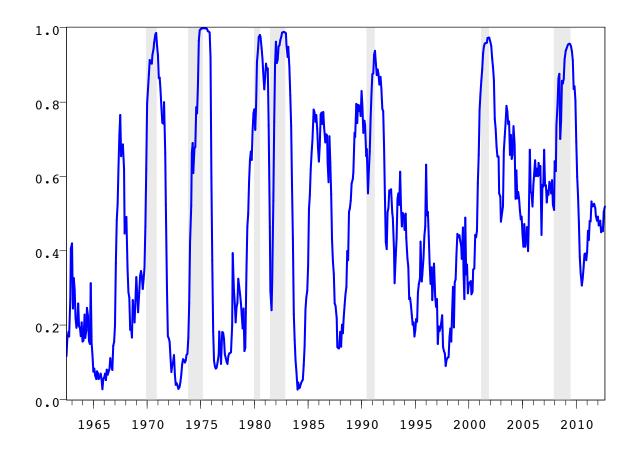

Figure A8 - Probability of being in a recessionary phase/monthly data. Blue solid line: Transition function F(z). Shaded columns: NBER recessions.

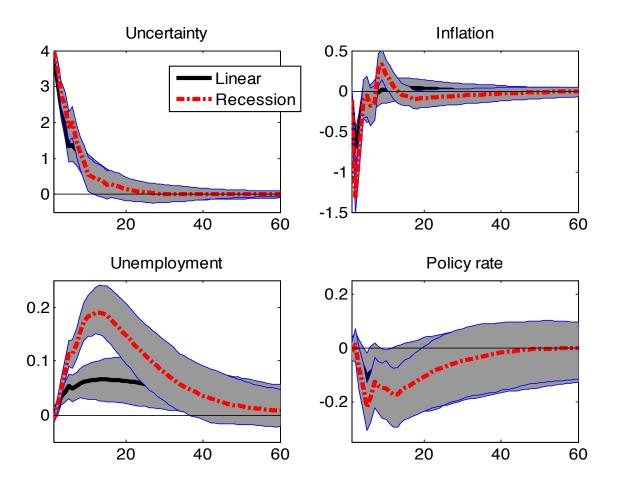

Figure A9 - Macroeconomic effects of uncertainty in recessions: Monthly data. Effects of a one standard deviation shock to VIX. Sample: 1962M7-2012M9. Solid black lines: Responses predicted by a linear VAR. Dash-dotted red lines: Reactions under recessions computed with our non-linear framework. Baseline VAR with four variables (uncertainty, CPI inflation, unemployment, policy rate). Gray areas: 68% bootstrapped confidence bands. Shocks identified with a Cholesky-decomposition of the variance-covariance matrix of the reduced-form residuals.
